# Bursting suppression in propofol-induced general anesthesia as bi-stability in a non-linear neural mass model

Pedro Garcia-Rodriguez<sup>\*</sup>, Axel Hutt

*From* The Twenty Third Annual Computational Neuroscience Meeting: CNS\*2014 Québec City, Canada. 26-31 July 2014

Bursting activity suppression, a phenomenon characterized by sequences of alternating quiescent ('*down*') and bursting ('*up*') states, is ubiquitously present during deep sedation in general anesthesia and can be observed in LFPs and in EEG recordings as well [1,2]. However, the dynamical principles underlying such phenomena

2D phase-portrait in the PSPs membrane potentials, showing the vector field (arrows) and sample free-hoise trajectories (blue) that converge to either of two existing attractors. An oblique line, containing unstable (saddles) states, largely separates the attraction basins. **B**. Noise-induced alternations between a larger (up state) and a smaller (*down* state) value can be tracked according to the current distance of the trajectory to the saddle line. **C**, **D**. Histograms of the residence times in each of the stable states. **E**, **F**. The mean residence times as a function of the propofol level (p) and the inverse of the excitatory synaptic impulse response time-scale ( $\alpha$ ).

are unclear. Prevailing theoretical approaches to this problem suggest that such bi-stable dynamics could be explained by the existence of notable non-linearities in the neuronal membrane potential as a function of the anesthetic agent, with frequent noise-induced transitions between two stable (attracting) branches. Nevertheless, the mathematical tractability of those models is rather limited due to the dimensionality (2D) of the phasespace (see Figure 1). It has been shown for a neuralmass version of the model proposed in [3], that the 2D-trajectory likely escapes to the other attractor trough a limited section of the saddle-line separating the attractions basins [4]. This prediction is here supported by numerical simulations, permitting the simplification of the dynamics to a simpler two-state trace. Relevant statistics can then be extracted, including histograms of the duration of the visit in each state that may support future analytical calculations of the EEG power spectrum following renewal theory [5]. Interestingly, it is found that only the average waiting time in the 'up' states is a non-linear decreasing function of p, differently to the residence time in the 'down' state that behaves linearly in p and in the synaptic time-scale  $(1/\alpha)$  direction as well.

## Submit your next manuscript to BioMed Central and take full advantage of:

- Convenient online submission
- Thorough peer review
- No space constraints or color figure charges
- Immediate publication on acceptance
- Inclusion in PubMed, CAS, Scopus and Google Scholar
- Research which is freely available for redistribution
